Abstract. This work introduces a robust algorithm for computing good polygonal approximations of implicit surfaces, where robustness entails recovering the exact topology of the implicit surface. Furthermore, the approximate triangle mesh adapts to the geometry and to the topology of the real implicit surface. This method generates an octree subdivided according to the interval evaluation of the implicit function in order to guarantee the robustness, and to the interval automatic differentiation in order to adapt the octree to the geometry of the implicit surface. The triangle mesh is then generated from that octree through an enhanced dual marching.

Keywords: Implicit Surface. Dual Marching Cubes. Robust Algorithms. Geometric Modelling.

1 Introduction

Implicit surfaces provide powerful primitives for geometric modelling. However, computing good polygonal approximations remains an important problem. An implicit surface is the set of solutions of an equation \( f(x, y, z) = 0 \), where \( f: \Omega \subseteq \mathbb{R}^3 \rightarrow \mathbb{R} \). For well-behaved functions \( f \), this set is indeed a manifold surface.

The simplest and most flexible polygonal approximation abides triangle meshes, since they are easy to represent efficiently and they suit also well for rendering with current graphics hardware. The criteria for good approximations involve robustness and adaptation. Robustness means that the mesh captures exactly the topology of the surface, guaranteeing the representation of each connected component in \( \Omega \) and their genus. Adaptation means that, with a reduced number of triangles, the geometry of the surface is described efficiently. In particular, the mesh should place large triangles in regions of low surface curvature and smaller triangles in regions of high surface curvature. Moreover, the triangles should have a good aspect ratio since thin triangles (also known as slivers) induce numerical instability for geometric processing, in particular for rendering and derivative estimations.

In this paper, we describe an algorithm that computes a robust and adaptive triangular approximation for an implicit surface given by a formula. The algorithm combines interval arithmetic and automatic differentiation to ensure both robustness and adaptation. The algorithm first explores the domain \( \Omega \) adaptively using an octree to locate the surface. This exploration uses interval arithmetic to eliminate octree cells that are guaranteed not to intersect the surface, driving the octree towards identifying all connected components. Combined with automatic differentiation, interval arithmetic provides interval estimates for the gradient, which allows locating regions of low curvature and detecting topological ambiguities. A triangle mesh is extracted from the dual of the
octree \[21\], and then smoothed to avoid slivers. This technique produces a good triangle mesh that carries topological and geometric guarantees. Figure \[1\] shows an example of the approximation of the implicit surface 
\[(1.5 - \sqrt{x^2 + y^2})^2 + z^2 - (1.35)^2 = 0,
\]
running our method in the cube \(\Omega = [-3.1, 3.1]^3\). Further examples are given in Section \[5\].

This paper extends to surfaces the work of Lopes et al. on implicit curves \[13\]. Section \[2\] reviews other related works. A brief account of interval arithmetic and automatic differentiation is given in Section \[4\] followed by the details of the complete algorithm in Section \[3\].

2 Related work

There exist mainly two types of data for defining implicit surfaces: discrete or continuous. Discrete data usually results from measurements or numerical simulations, which increase the interest for visualizing such data in medical and scientific applications. Discrete data contains information only at the vertices of a grid and requires interpolation schemes for the other points. In contrast, continuous data can be evaluated at arbitrary points of \(\Omega\). Implicit surfaces given by continuous data are especially relevant for geometrical operations such as deformations, interpolations and derivation mechanisms. Classical methods for the continuous case sample the function at the vertices of a regular grid and apply algorithms for the discrete case. However, the knowledge of the continuous function may help in generating adapted grids.

Extensions of Marching Cubes. Probably the earliest and most influential work on approximating implicit surfaces from discrete data remains the Marching Cubes algorithm by Lorensen and Cline \[13\]. Marching Cubes works on a cubical grid and identifies cells that intersect the surface by testing the signs of the values at the eight vertices of each cube. If the signs are not all the same, then the surface is approximated within the cell by planar patches: the signs of the eight vertices form an 8-bit word which serves as a key for the configuration of the cube, and a lookup table stores the patches for each possible configuration.

The main issues in this approach are ensuring consistency of the approximation across neighbouring cells and resolving topological ambiguities. Many papers have been written on improving Marching Cubes along these lines, and early papers are discussed in a survey by Ning and Bloomenthal \[13\]. In this paper, we use a recent implementation of Marching Cubes by Lewiner et al. \[12\] that introduced topological guarantees.

Adaptive strategies. The earliest papers that perform adaptive approximation of implicit surfaces are due to Bloomenthal \[3\], who used cubical cells, and to Hall and Warren \[7\], who used tetrahedral cells. Both papers took care to avoid cracks on the approximating mesh. Hall and Warren also tried to eliminate slivers by projecting mesh vertices that are near the surface. Several other authors discuss adaptive subdivision and refinement \[20\,23,26\]. Hartmann \[8\] described a continuation algorithm that produces a regular mesh, extended by Karkanis and Stewart \[25\] and Araujo and Jorge \[1\] to adaptive meshes. Quite recently, Ho et al. \[9\] extended Marching Cubes to generate adaptive approximations that preserve sharp features and provide topological consistency. We used a different approach to ensure crack-free approximations by the use of dual grids, pioneered by Ju et al. \[10\], Schaefer and Warren \[21\], and Nielson \[17\].

Robustness. Very few methods guarantee robustness in the continuous case. Standner and Hart \[22\] used interval methods to guarantee the correct topology of polygonal approximations during interactive modelling. Their use of Morse theory is further developed for implicit surfaces in the work of Boissonnat et al. \[4\]. Lopes et al. described a robust method for implicit curves \[13\], which motivated the present work.

3 Numerical tools

The main numerical tool that we shall use to ensure both robustness and adaptation is the combination of interval arithmetic \[15\] for localizing isolated pieces of the mesh, and automatic differentiation \[24\,25,19,11\] for guaranteeing the topology of each piece and providing geometric adaptation. In this section we briefly review how these tools work.

Interval arithmetic. Given a function \(f : \Omega \subseteq \mathbb{R}^3 \to \mathbb{R}\) and a rectangular box \(B\) contained in \(\Omega\), interval arithmetic computes an interval \(F(B) \subseteq \mathbb{R}\) such that
\[F(B) \supseteq f(B) = \{f(x, y, z) : (x, y, z) \in B\}\].

In other words, interval arithmetic provides a reliable estimate for the complete set of values taken by \(f\) in \(B\). It does so by extending all basic arithmetic operations and elementary functions to work on intervals instead of real numbers. To compute the interval estimate \(F(B)\), we write \(B = X \times Y \times Z\), where \(X, Y, Z\) are intervals, and simply perform the same operations needed to evaluate \(f\), except that we use the interval version of those operations and that we operate with intervals \(X, Y, Z\) instead of numbers \(x, y, z\). By carefully rounding interval extremes outward, we obtain interval estimates that are reliable even when computed in floating-point machine arithmetic, which is subject to rounding errors.

Implicit surface test. The power of using interval estimates in approximating an implicit surface \(S\) given by \(f(x, y, z) = 0\) is that they provide the following reliable test for \(B\) not containing any part of \(S\): if \(x \not\in F(B)\), then \(0 \not\in f(B)\). This test, which is a simple consequence of \(F(B) \supseteq f(B)\), is used as a stopping criterion for an octree subdivision of \(\Omega\) (see Section \[4\]). Note that this is not an approximate statement: \(0 \not\in F(B)\) is a proof that \(B\) does not intersect \(S\); there

Automatic differentiation. There are three main alternatives for computing the gradient of \( f \): symbolic differentiation, which generates expressions for the partial derivatives of \( f \); numerical differentiation, which finds approximations for the values of these partial derivatives; and automatic differentiation, which combines the speed of numerical differentiation with the accuracy of symbolic differentiation. Automatic differentiation works by defining an arithmetic for tuples of intervals instead of tuples of numbers. The width obtained by applying the automatic differentiation formulas on tuples of intervals instead of tuple of numbers. The width of these interval estimates helps building a geometrically adaptive octree.

4 Robust adaptive polygonisation

This section details first how we combine these numerical tools to generate an adapted octree, and then how we extract an approximation of the implicit surface given by \( f(x, y, z) = 0 \) in \( \Omega \). We assume that \( f \) is twice continuously differentiable (\( f \in C^2 \)) and admits zero as a regular value, which means that the gradient of \( f \) does not vanish on the implicit surface. This is actually a generic assumption, that is, it is restored by infinitesimal perturbations.

(a) Building the octree

Our algorithm starts with the whole domain \( \Omega \), and assigns it to the root of the octree. Then, at each step of the subdivision, it checks whether the cell \( n \), having domain the box \( B_n \), must be subdivided. If so, the algorithm recurses on the subdivisions of \( n \). A cell must be subdivided if it satisfies one of the three following criteria: connected component criterion, topology criterion and the geometry criterion. These criteria are derived from the interval evaluation \( F(B_n) \) and \( \nabla F(B_n) \) of both the function \( f \) and its gradient \( \nabla f \) on the box \( B_n \).

Connected component criterion. This criterion selects the cells of the octree that may contain a patch of the implicit surface, and discards the cells that surely do not intersect the surface. As detailed in Section 3 this can be tested robustly with the interval evaluation \( F(B_n) \) of \( f \) on the box \( B_n \):

\[
\text{if } 0 \notin F(B_n) \text{ then discard}(n)
\]

This test is robust, meaning that it is guaranteed not to discard any connected component of the implicit surface \( f^{-1}(0) \) in \( \Omega \): one of its points \((x, y, z)\) would be contained in a cell \( n \) \(((x, y, z) \in B_n)\), and thus \( 0 = f(x, y, z) \in f(B_n) \subseteq F(B_n) \), which avoids discarding \( n \).

Topology criterion. A connected component of the implicit surface can have arbitrary genus, in particular it may contain tunnels. The previous criterion alone does not guarantee to
recover tunnels. However, combined with the topology criterion, it can safely discard the empty parts of these tunnels. If a box $B$ contains a tunnel, then the gradient of \( f \) varies inside $B$ from one vector $(n_x, n_y, n_z)$ at point $(x, y, z)$ to its opposite $(-n_x, -n_y, -n_z)$ on the facing point $[4]$. Therefore, the coordinates $I_x, I_y, I_z$ of the interval estimation of $\nabla f$ contain opposite values. Since $I_x, I_y, I_z$ are intervals, $0 \in I_{x,y,z}$.

The topology criterion is thus:

$$\text{if } (0, 0, 0) \in \nabla F(B_n) \text{ then } \text{subdivide}(n)$$

**Geometry criterion.** To approximate correctly the geometry of the implicit surface with a reduced number of triangles, we need to allow small triangles only in regions of high curvature. The curvature can actually be estimated from the geometry criterion is:

$$\text{if } \text{Diam} \left( \frac{\nabla F(B_n)}{||\nabla F(B_n)||} \right) > k_{\text{max}} \text{ then } \text{subdivide}(n)$$

Note that the topology criterion guarantees that $0 \notin \|\nabla F(B_n)\|$, which validates the above expression. The parameter $k_{\text{max}}$ actually weights the geometric adaptation, as illustrated on Figure 4.

**Algorithm end.** The above criteria may induce a large number of subdivisions, even infinite if the implicit surface has infinite genus (which is a highly non generic case). Moreover, since the interval evaluation $F(B)$ only contains the exact image $f(B)$ with conservative rounding error, subdivisions may be required on empty areas when numerical precision decreases. In practice, the algorithm subdivides the octree until a given maximal level, which may correspond to the size of the pixel for rendering applications, minimal size of the triangles for geometry processing, or numerical precision for simulation. However, the above criteria still point out which parts of the implicit surface are not guaranteed, while guaranteeing the approximation of the others. This robust behaviour allows stopping the subdivision of the octree before the given maximal level if the approximation is already validated (see Figure 4).

(b) From octree to dual grid

To generate the mesh we use an enhanced version of the Schaefer–Warren method [21]. Like them, we first create the dual grid of the octree, which is the topological dual of the octree: the vertices of the dual grid are the centre points of the octree cells, and the edges correspond to the adjacency between these cells. This way the each volumetric cell of the dual grid is associated with an interior vertex of the octree. Figure 5 illustrate this duality in the simpler case of quadtreess.

---

Figure 3: The effect of the geometric criterion on the smile surface \((y - x^2 - y^2 + 1)^4 + (x^2 + y^2 + z^2)^4 - 1 = 0\). The mesh is uniform without this criterion (left), while it tracks regions of higher curvature when $k_{\text{max}}$ increases, here from $k_{\text{max}} = 0.5$ (middle) to $k_{\text{max}} = 0.95$ (right).

Figure 5: A primal quadtree (thin black) and its dual grid (thick green).
Since the dual grid is generated once for the whole octree, this task is further optimized by traversing the octree from the root maintaining at each step the adjacencies of the nodes.

(e) Mesh generation

The dual grid is then a coherent set of dual cells meeting at dual vertices, dual edges and dual faces. From the dual grid, we extract a mesh approximating the implicit surface by creating triangles in each of these dual cells. We use the public code of Lewiner et al. [12] to do so, which suits well here since the cells are convex and have at most 8 vertices. This algorithm will thus guarantee a manifold output with no crack, while working only locally. The mesh can be then further optimized in terms of aspect ratio by an inexpensive process described at the end of this section.

![Figure 4](image)

Figure 4: On complex models, such as the two torus surface \( g(10x, 8y - 2, 10z, 13) \cdot g(10z, 10y + 2, 10x, 12) + 1000 = 0 \) with \( g(x, y, z, c) = (x^2 + y^2 + z^2 + c)^2 - 64(x^2 + y^2) \), the topology may not be guaranteed at a given resolution. At level 6 (left), our algorithm marks ambiguities regions (in red), and subdivides them, here stopping at level 7 (centre) and 8 (right) where the whole surface is robustly guaranteed.

![Figure 6](image)

Figure 6: Key generation for the 2D lookup table: for the regular Marching Cubes case (left), the key is generated with the four entries \((f_{tr}, f_{tl}, f_{bl}, f_{br})\). In the dual case (left), the value of the higher level node (the left one) has to be duplicated to generate a four-entry key \((f_{tr}, f_{tl}, f_{br}, f_{br})\).

Cell key generation. Lewiner et al. [12] use a lookup table \(L\) that extends the one of the original Marching Cubes [14]: for each cube, they compute a key \(k\) from the values of its eight vertices and creates the triangles of the approximating mesh from the lookup table match \(L[k]\) of the key.

The only difficulty here is to generate a key with eight entries since the dual cells may have less than eight vertices. This occurs when the dual vertices correspond to octree cells \(c_i\) of different levels (see Figure 5). If we subdivided these octree cells until they had all the same level, the dual cell would be a cube. The key for the lookup table is then generated by duplicating the values of the dual vertices which belong to the same octree cell \(c_i\). In practice, we compute all the keys directly when generating the dual grid, without any extra octree subdivision.

Triangle creation. We use this key in the lookup table, and create the indicated triangles. Note that the tests of the asymptotic decider of Nielson and Hamann [16] are sufficient to guarantee the manifoldness of the results, but in case the subdivision of the octree is limited in space, the lookup table of Lewiner et al. [12] should recover the topology of the intersection better. The vertices of the indicated triangles can be computed exactly on the implicit surface, using a simple bisection method either along the dual edge, or along the normal estimated by automatic differentiation.

Further mesh improvements. The above process already guarantees a correct topology and an adaptive distribution of triangle sizes along the mesh. Although the mesh quality already passes the Marching Cubes one (see Figure 7), it can be further improved by sliding its vertices to have better shaped triangles. We use a technique similar to the one used by Botsch and Kobbelt [5]: for each vertex \(v\), its normal \(\vec{n}_v\), and the barycentre \(b_v\) of its star are computed. The vertex is then shifted tangentially towards \(b_v\), which writes \(v \leftarrow v + (\vec{b}_v - (\langle \vec{b}_v, \vec{n}_v \rangle \cdot \vec{n}_v))\). The tangential movement avoids strong shrinking, and the relaxation towards \(b_v\) improves the aspect ratio of the triangles. The vertices are then projected...
back onto the implicit surface by the bisection mentioned above (see Figure 7). Note that this process is applied on all the vertices at once, and thus does not require adjacency structure for the mesh.

5 Results

We checked the validity of our method on various models. In particular, the robustness paradigm is clearly illustrated on Figure 1. The red regions on this figure indicate that the approximation obtained on that region is not guaranteed, although the algorithm provides a valid global surface. The red region marks that either the topology or the geometry criterions on the corresponding primal node of the octree failed. Observe on the left image that the obtained surface has genus 0 for that level of approximation (4). These ambiguities can be solved by allowing more subdivision. Even if our algorithm is conservative, as illustrated on Figure 4, the ambiguities are solved in practice with only a few subdivisions (until level 6 and 8 for Figures 1 and 4).

The proposed geometric criterion produces well adapted meshes, as the one of Figure 2 with a reduced number of triangles (see Table 1). Its effect is monitored by $k_{\text{max}}$, the only manual parameter of our algorithm. Figure 2 shows how the triangles concentrate on the regions of high curvature when increasing this parameter. This adaptability cannot be achieved directly by the Marching Cubes method, as illustrated by Figure 4. On this figure, the histogram of the aspect ratio $\frac{\text{area}}{\text{min}(\text{area})}$ shows that the our method already produces high quality mesh, which can be improved by the method of the end of section 4. Robust adaptive polygonisation. Moreover, the quality of the mesh does not result from a symmetry artefact, as illustrated on Figure 8.

Our algorithm handles nicely degenerated cases, such as the singular points (pinch) of the tear drop model of Figure 2. Even if we do not recover the feature, the algorithm marks that the approximation needs refinements. The case is similar for non–manifold surfaces, as the two intersecting planes of Figure 10. The algorithm reconstructs a manifold approximation, on which the non–manifold parts of the real implicit object are marked as ambiguous.

6 Conclusion

This work addressed the problem of computing good polygonal approximations of implicit surfaces. We proposed a robust algorithm that can either guarantee the exact topology of the implicit surface or point to the user ambiguous parts, which can be solved by further refinements. The robustness is achieved by the combination of interval arithmetic with automatic differentiation into adaptation criteria. We then extract an approximate triangle mesh from this octree through a dual Marching Cubes algorithm. We finally improve the quality of the triangles in the final mesh by simple and efficient geometry processing.

We do guarantee the topological consistency for manifolds: the mesh does not contain cracks and it does have the correct genus. While we do not promise to handle all singular cases, our algorithm clearly show regions that may contain singular points or curves. Since we are dealing only with continuous data, as opposed to discrete data, we do not use any heuristic. In particular, we can use bisection to locate, with great accuracy, the intersections of the surface with the boundary of a cell.

References

Our algorithm does not suffer from symmetry artefacts. For example, on the chair surface \((x^2 + y^2 + z^2 - ak^2)^2 - b((z - k)^2 - 2x^2)((z + k)^2 - 2y^2) = 0\) with \(a = 0.95\), \(b = 0.8\), and \(k = 5\), it detects the same ambiguities and shows similar triangulations independently on the cube position \(\Omega: [-10.2, 5.8] \times [-10.2, 5.8] \times [-8, 8]\) (left), \([-8, 8]^3\) (middle) or \([-5.8, 10.2] \times [-5.8, 10.2] \times [-8, 8]\) (right).

![Figure 9: The singularities of the teardrop surface \(0.5x^2 + 0.5x^4 - y^2 - z^2 = 0\) are detected by our criterion, but the meshing does not recover them completely.](image)
